## **Abstract**

This project consists of designing and implementing a real-time graphical interface for a workstation-based flight simulator. It is capable of creating a three-dimensional out-the-window scene of the aircraft's flying environment, with extensive information about the aircraft's state displayed in the form of a heads-up-display (HUD) overlay. The code, written in the C programming language, makes calls to Silicon Graphics' Graphics Library (GL) to draw the graphics primitives. Included in this report is a detailed description of the capabilities of the code, including graphical examples, as well as a printout of the code itself.

## Introduction

In order for the Aeronautical engineering student to competently analyze and design aircraft, he must be familiar with the way aircraft fly. In other words, he must have an intuitive, as well as mathematic, understanding of aircraft performance and, to some degree, aircraft handling qualities. A powerful tool for this is the flight simulator. An engineer can choose a specific set of flight conditions and maneuvers, or pilot tasks, and with the corresponding set of stability derivatives, analyze how well the aircraft flies.

Many flight simulators work by mathematically analyzing the flight conditions and stability derivatives, then giving a time history of important variables as output. While this information is useful, it often fails to provide the engineer an intuitive feel for what the aircraft is actually doing. By providing a graphical interface, such as an animated three-dimensional model of the world outside the aircraft, the engineer can actually see the dynamic responses. He can easily vary his inputs and rapidly and intuitively understand the effects of the changes.

Another important learning tool is the incorporation of real-time input into such a simulator, as opposed to a batch mode operation. This feature would allow the engineer to be in the loop, to become the pilot. In addition to flying the aircraft at the given flight conditions, the engineer would have the ability, through the mouse, keyboard, or flight stick, of actually changing the control inputs and immediately see the effects of his changes. In this way, the engineer can rapidly assess both qualitatively and quantitatively how well the aircraft performs.

This project consists of designing and implementing a real-time graphical interface for a workstation-based flight simulator. It is capable of creating a three-dimensional out-the-window scene of the aircraft's flying environment, with extensive information about the aircraft's state displayed in the form of a heads-up-display (HUD) overlay. The code, written in the C programming language, makes calls to Silicon Graphics' Graphics Library (GL) to draw the graphics primitives. Included in this report is a detailed description of the capabilities of the code, including graphical examples, as well as a printout of the code itself.

## Simulated Airport

As shown in Figure 1, the out-the-window scene consists of a ground plane with a grid for visual reference, an airport, and some simple mountains in the distance. The airport is modeled after Moffet Naval Air Station, where NASA-Ames is located, and contains its two parallel runways, the blimp hangar, and two P-3 Orion submarine-hunter hangars. To give a sense of scale, the blimp hangar is 300 ft wide and 1,200 ft long. The runways at Moffet are built along a magnetic course of 320/140. Viewed from the south, the runway on the left (32L) is 8,125 ft long and 200 ft wide. The runway on the right is 9,200 ft long and 200 ft wide.

For simplicity in setting up the landing approach task in the simulator, some artistic license was taken, and the runways are drawn to align with magnetic north. For this reason, runways 32L and 32R become 36L and 36R, respectively. Therefore, when lined up with the runway in an approach from the south, the heading indicator in the simulator will read a bearing of 360. To improve the update rate of the graphics, markings are added only to the left runway (36L), and the right one left blank. The markings are constructed according to the standards for a precision-approach equipped runway, with some simulated tire marks for visual effect.

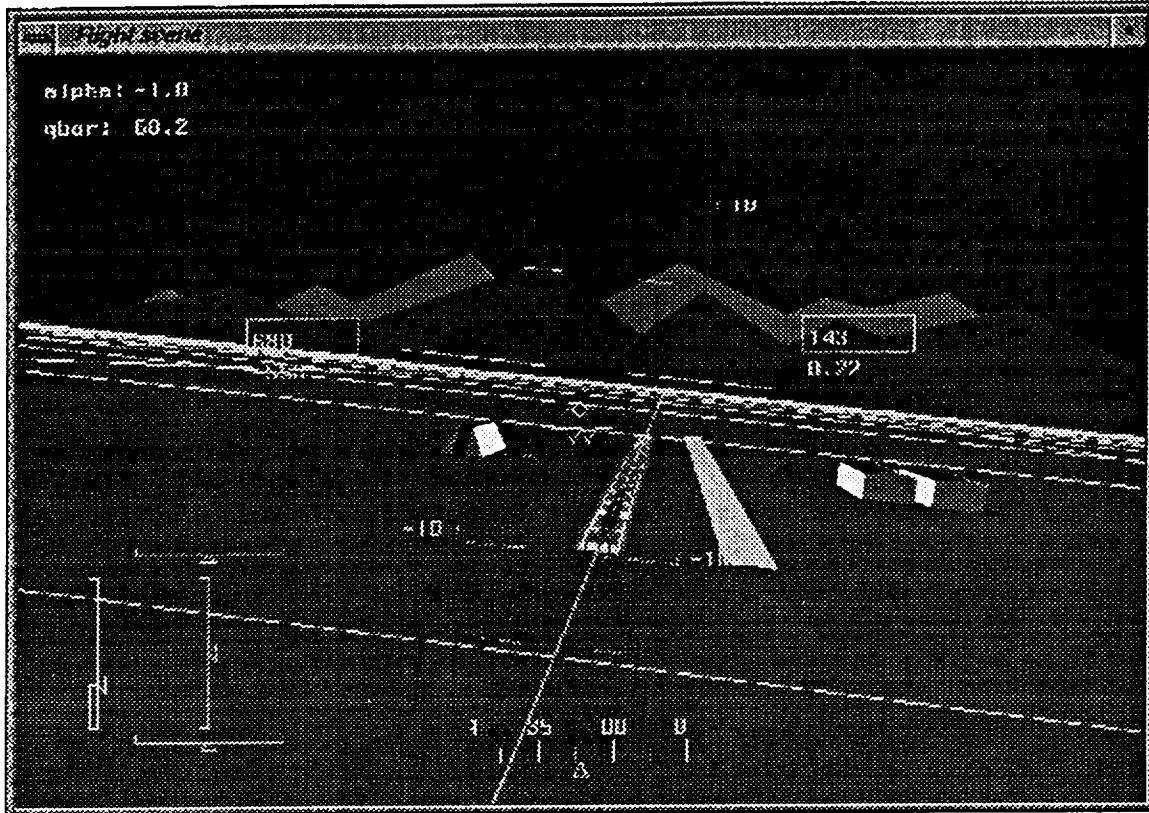

Figure 1 - Out the Window Scene Showing the Simulated Airport and HUD Symbology Overlay

### Landing Task

To aid in the evaluation of a simulated aircraft's handling qualities, an approach to landing is one of the available tasks for the simulator pilot. A score is determined by integrating the squares of the distances above or below glideslope, and left or right of the runway centerline. To accomplish the landing task accurately, the pilot must be provided with an indication of position relative to the desired glideslope. Off of the approach end of runway 36L is a set of "telephone poles" that create a visual reference, as shown in Figure 1. The poles are arranged in two rows, angled outward from the touch-down point to create a tapered hallway that narrows as the aircraft approaches the runway. The poles get progressively taller away from the touch-down point, defining a plane that is the standard 3° glide slope. The approach can be set up steeper, to simulate an aircraft-carrier approach for example, by changing the glide slope angle in the input file that controls the simulation (`sim_ctrl.dat`). When the pilot is approaching the runway on the defined glide slope, the tops of the poles will line up parallel to the horizon. If the pilot is below glideslope, the tops of the poles will appear to angle upward. If flying above the glideslope, they appear to angle downward. With a little familiarization, the visual cues are quite sensitive to vertical deviations, especially closer to touch down. The two rows also create an additional visual cue that assists in lining up with the runway from a distance.

## HUD Symbology

On top of the out-the-window display is a collection of symbology that simulates a heads-up-display (HUD). As shown in Figure 1 and Figure 2, in the top left corner of the screen are digital indications of angle of attack (alpha) and dynamic pressure ( $q_{\bar{b}}$ ), the two independent variables that define the table look up for stability derivatives in the simulation. When the aircraft flies outside the defined envelope of data, these values turn red, indicating to the pilot that the current flight state is not being properly modeled. The aircraft altitude is displayed in feet in a box on the left side of the screen, with the rate of climb in feet per minute under it. In the box on the right side is the true airspeed in knots (nautical miles per hour), with the Mach number shown below.

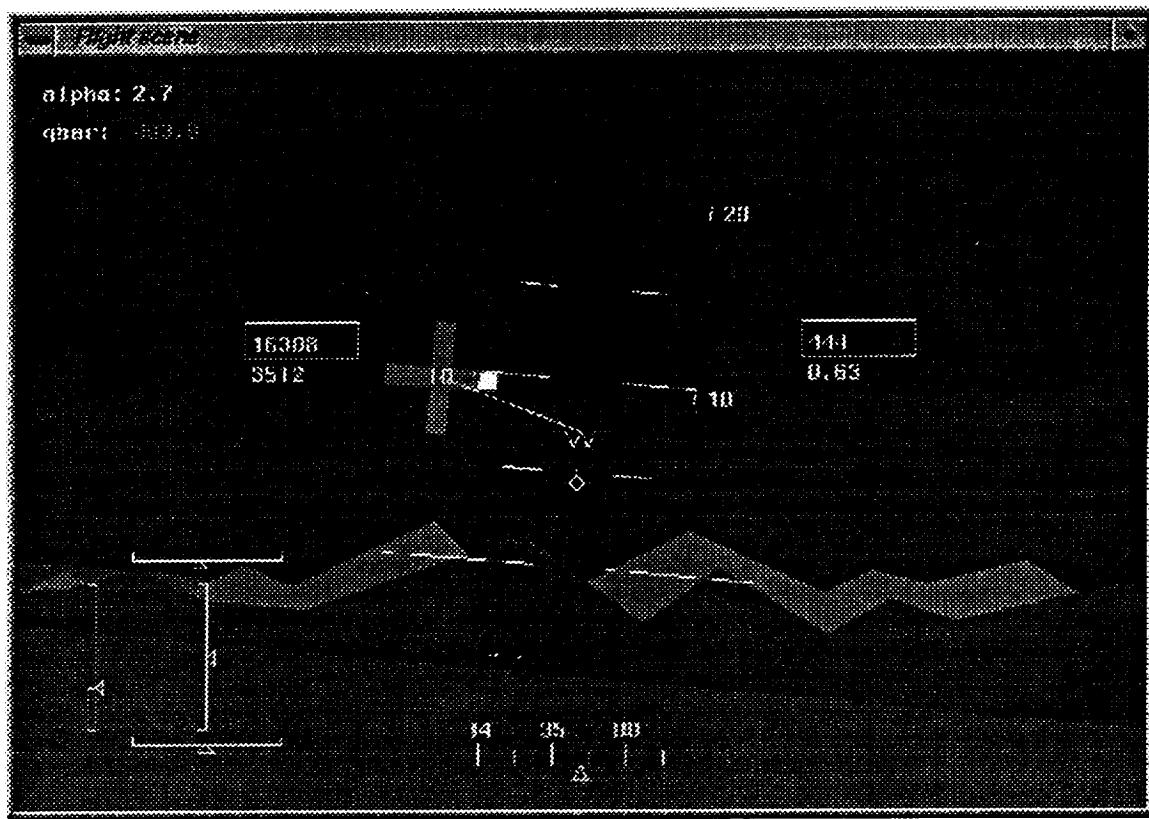

Figure 2 - Target for Up-and-Away Task with HUD Overlay

The center of the screen is dominated by the pitch ladder, which indicates the aircraft's pitch and bank angles. The "W" shaped symbol is the "waterline," and it represents the direction the nose of the airplane is pointed. In other words, the rung of the pitch ladder that it lies on corresponds to the Euler angle  $\theta$ , or the angle between the aircraft body axis out the nose and the horizontal plane. The small diamond with three short lines coming out of it is the velocity vector, and it shows the actual direction of flight. The vertical displacement between this symbol and the waterline is therefore the angle of attack  $\alpha$ , and the horizontal displacement indicates the angle of sideslip  $\beta$ . Since the rungs of the pitch ladder remain aligned with the

horizon, the aircraft bank angle  $\phi$  is reflected in the ladder's rotation. At the bottom center of the screen is a heading indicator, or compass, that indicates the Euler angle  $\Psi$ .

In the bottom left corner of the window is a set of symbols that display the commanded thrust, actual thrust, and the positions of the ailerons, elevator and rudder. The vertical slider farthest to the left is the thrust indicator. The small triangle moves up and down in response to the throttle inputs from the pilot, from 0% at the bottom to 100% at the top. The rectangle on the left side of the line represents the actual thrust, and may lag behind the pilot's commands if the simulated engine is modeled to take time as it spools up and down. The other vertical slider shows the actual position of the elevator, which may be different from the commanded position if a feedback control law is implemented. For a conventional stable aircraft, full elevator deflection trailing edge down (stick forward, nose down pitching moment) drives the pointer to the top of the line, and vice-versa. The horizontal slider at the top of this cluster indicates the actual differential aileron deflection, with a full left-rolling deflection driving the triangle to the left end of the line, right-rolling to the right end. Similarly, the slider at the bottom of the cluster indicates actual rudder deflection. Rudder trailing edge full left (nose left yawing moment) drives the slider to the left end of the line, full right deflection to the right end.

### **Up-and-Away Task**

The "up-and-away" task, which simulates an air-to-air engagement, is shown in Figure 2. The target is a cruciform shape, with a yellow light on each arm. The target moves relatively slowly, creating a gross acquisition/low frequency tracking task for the simulator pilot. If the target is lost from the field of view, the line drawn from the middle of the HUD to the center of the target will indicate the direction to fly to reacquire it. The yellow lights on the cross alternate randomly such that they illuminate one at a time, creating a faster, more demanding tracking task. The pilot must supply inputs at higher frequencies, which may uncover flaws in the simulated aircraft's handling qualities. The up-and-away task is designed to represent a real-world experiment, flying behind a test aircraft with lights on the top and bottom of the vertical tail, as well as the left and right tips of the horizontal stabilizer.

The simulator formulates a quantitative score based on the cumulative difference between the position of the target and the direction the aircraft's nose is pointed. Instead of modeling the up-and-away target at a three-dimensional world object, the position of the cross is driven by a commanded pitch angle and heading angle passed from the simulation. This eliminates the need for accurate speed and altitude control, while still providing for a challenging tracking task that will work for any aircraft. It also eliminates the need for three-dimensional vector operations to calculate the angular error between the aircraft's attitude and the commanded attitude. In this manner, the cross always maintains the same distance off the nose, and oscillates about the aircraft's current altitude.

## Computer Code

This section contains the computer routines and include files that create the graphics for the real-time flight simulation. For more extensive explanations of specific GL function calls, refer to the Silicon Graphics Iris-4D Series manuals, Graphics Library Programming Guide and Graphics Library Reference Manual: C Edition. At the time of this writing, copies of these manuals are available in the Flight Simulation Lab, located in the AMDAF building on campus. For more information, including access to the source code for the entire flight simulation, contact Dr. Biezad at (805) 756-5126.
